Estimating mean bedload transport rates and their uncertainty

Christophe Ancey and Ivan Pascal

1Ecole Polytechnique Fédérale de Lausanne, 1015 Lausanne, Switzerland

Key Points:
- We calculate the ensemble-averaged mean and variance of bedload transport rates using Markov process theory
- Bedload transport rate variance varies inversely to the sampling duration
- We propose a protocol for defining mean bedload transport rates and their variance under various flow conditions

Corresponding author: C. Ancey, christophe.ancey@epfl.ch
Abstract
Measuring bedload transport rates usually involves measuring the flux of sediment or collecting sediment during a certain interval of time $\Delta t$. Because bedload transport rates exhibit significant non-Gaussian fluctuations, their time-averaged rates depend a great deal on $\Delta t$. We begin by exploring this issue theoretically within the framework of Markov processes. We define the bedload transport rate either as the particle flux through a control surface or as a quantity related to the number of moving particles and their velocities in a control volume. These quantities are double-averaged, that is, we calculate their ensemble and time averages. Both definitions lead to the same expression for the double-averaged mean rate and to the same scaling for the variance's dependence on the length of the sampling duration $\Delta t$. These findings lead us to propose a protocol for measuring double-averaged transport rates. We apply this protocol to an experiment we ran in a narrow flume using steady-state conditions (constant water discharge and sediment feed rates), in which the time variations in the particle flux, the number of moving particles, and their velocities were measured using high-speed cameras. The data agree well with the previously defined theoretical relationships. Lastly, we apply our experimental protocol to other flow conditions (a long laboratory flume and a gravel-bed river) to show its potential across various contexts.

1 Introduction

1.1 Bedload Transport Rate and Fluctuations

Whether measuring bedload transport rates in the field or the laboratory, we are faced with a three-part problem. Firstly, there is no universally accepted definition of the bedload transport rate $Q_s$, and various definitions have been used depending on the context (Ballio et al., 2014; Furbish et al., 2017; Ballio et al., 2018). For instance, in the laboratory, it has long been common to collect the sediment transported to the flume outlet over a given time interval and weigh it to deduce a time-averaged value of $Q_s$. Today, techniques based on impact plates, acoustic sensors and image processing enable high-frequency measurements of $Q_s$ (Singh et al., 2009; Gray et al., 2010; Tsakiris et al., 2014; Rickenmann et al., 2014; Mendes et al., 2016; Geay et al., 2017). In both cases, $Q_s$ is defined as the particle flux through a surface. Alternatively, in the field, using tagged particles (tracers) has long been the simplest way of measuring transport rates (Wilcock, 1997), with $Q_s$ reflecting the complex history of the particles entrained by the flow and subsequently deposited (or possibly buried) on the streambed (Einstein, 1950). Secondly, measuring sediment transport rates (i.e., the displacements and velocities of sediment, and the number of moving particles) remains an enormous technical challenge. Geophones and seismic sensors can only provide proxy calculation methods, which can be related to $Q_s$ after signal processing (Gray et al., 2010). Discriminating between the various processes (multiple impacts, differently sized sediment, rolling or saltating sediment) is fraught with difficulty (Wyss et al., 2016; Dhont et al., 2017; Dietze et al., 2019). Thirdly, recorded transport rates exhibit very significant non-Gaussian fluctuations even under steady-state flow conditions (Ancey et al., 2008; Ancey & Heyman, 2014). When both the sediment feed rate and water discharge vary over time, it becomes extremely difficult to separate the various random particle movement and bedform migration components of fluctuation and to disentangle the timescales associated with each process (Dhont & Ancey, 2018).

Although the existence of wide fluctuations in bedload transport rates—and their influence on their mean rate estimates—has long been known (Gomez, 1991; Bunte & Abt, 2005; Singh et al., 2009; Recking et al., 2012), some scientists show little awareness of the crucial influence of measurement protocols, particularly the definition of sampling duration, when estimating mean transport rates and their associated uncertainties. Very few experimental papers have specified how accurate their bedload transport rate measurement was. In many cases, authors mentioned that because they had achieved steady-
Figure 1. Variation in the time-averaged particle flux (solid line) \( \Phi_s = (\Delta t)^{-1} \int_0^{\Delta t} \Phi_s(t) \, dt \) with sampling duration \( \Delta t \). The instantaneous particle flux \( \Phi_s(t) \) was measured by counting the number of particles crossing a control surface located at the flume outlet during a time interval \( \Delta t = 4 \) ms. The flume was 2.5 m long and tilted at 1.55° to the horizontal (see §3 for further information on the experiment). The horizontal dashed black line shows the feed rate \( Q_{in} = 10.3 \) grains/s. The inset shows the time variations in the instantaneous particle flux \( \Phi_s \). The red dots show the mean particle fluxes computed using our proposed protocol based on the bootstrap method (see §2.7).

The uncertainty principles in physics (e.g., Heisenberg’s principle) and signal processing (e.g., Gabor’s principle) set limits to the precision with which certain physical properties can be measured simultaneously. One can intuitively understand that calculating bedload transport also involves a trade-off between the level of noise and the representativeness of time-averaging: if a short sampling duration is selected, the time-averaged flux \( \Phi_s \) to deviate substantially from its steady-state value \( Q_{in} \). Convergence towards the steady-state value \( Q_{in} \) was quite slow: sampling durations should exceed 20 min to get the mean particle flux to within 5%; with other flumes and experimental conditions, we had to wait 100 hours (Dhont & Ancey, 2018). Thus, although it has often been overlooked in research papers to date (Ancey, 2020), we believe that proper estimation of the uncertainties associated with bedload transport measurements should be a central issue in any experimental protocol.
ration is selected, the variance of $\Phi_s$ is small, but $\Phi_s$ may be biased, especially under time-dependent flow conditions (Ballio et al., 2014).

1.2 Objectives

The present paper proposes a method for estimating the average and variance of a particle transport rate $Q_s$ when a $Q_s$ time series is available. We consider two definitions of bedload transport rate (see § 2): firstly, measuring a particle flux through a control surface (e.g., using geophones or image processing), or secondly, measuring particle displacements and velocities in a control window (e.g., using a high-speed camera or an acoustic doppler velocimetry profiler). We are aware that these definitions may not cover all conditions and measurement techniques, but at least they correspond to techniques commonly in use today. The theoretical underpinnings are based on the stochastic bedload transport model developed by Ancey et al. (2008). When sufficient statistical information can be inferred from experimental data, an alternative to calculating the time-averaged particle flux is the use of renewal theory (see Appendix B). Both methods involve high-frequency measurement of the instantaneous transport rate (typically higher than 1 Hz). When high acquisition frequencies are impossible, the central limit theorem provides the asymptotic variation of the $q_s$ variance with sampling duration $\Delta t$. This method has been successfully applied to various set-ups in well-controlled laboratory experiments (see § 4). We present two other applications to demonstrate that the proposed method can be used in various settings (see § 5).

1.3 A Toy Model

To give a foretaste of the ideas developed in this paper, we consider a virtual experiment. Particles arrive randomly in a flume at a rate $\nu = 1$ grain/s and cross a control surface $S$ (see Fig. 2(a)). By counting the number $N$ of particles that have crossed $S$ during the time interval $\Delta t$, we can estimate the mean particle flux as $\Phi_s = N/\Delta t$. Because bedload transport exhibits large non-Gaussian fluctuations, even under steady state conditions, we obtain different $\Phi_s$ values depending on when we start the measurement or which path is selected. Figure 2(b) shows eight replicates from the same experiment: particle arrival is described as a Poisson process (as we will see later, this is a fair assumption when bedload transport is weak), all paths are realizations of the Poisson process with rate $\nu = 1$ grain/s, and thus the number of particles crossing $S$ over a time interval $\Delta t$ varies from one run to another. If we consider the specific run whose endpoint is B (at time $t = 20$ s) in Fig. 2(b), we find that $N = 4$ for $\Delta t = 10$ s (point A), and thus $\Phi_s = 4/10 = 0.4$ grains/s, a value 60% off the mean rate $\nu$.

How can we improve accuracy? The simplest idea is to increase the time interval $\Delta t$. By taking $\Delta t = 20$ s, we find $N = 15$ (point B) and thus $\Phi_s = 15/20 = 0.75$ grains/s. The error has dropped to 25%. This is consistent with what Bunte and Abt (2005) and Singh et al. (2009) showed in their field and laboratory experiments: the sample mean and variation vary with increasing sampling durations, and the longer the sampling duration, the lower the error. There are two problems with this approach. Firstly, in practice, it is difficult to take long sampling durations, especially if the flow is time dependent. Secondly, when computing the time-averaged flux $\Phi_s = N/\Delta t$, we have no idea how close this estimate is to the actual rate $\nu$. Indeed, the sample variance is computed by using the $\Phi_s$ values along a particular path, and it does not tell us anything about the relative error $\epsilon = |1 - \Phi_s/\nu|$. For instance, for path AB, the sample variance is $\sigma_\Phi^2 = \sum_{t=1}^{M}(N(t) - \Phi_s)^2 = 3.72$ grains$^2$/s$^2$ ($M$ is the number of sampled values), yielding a coefficient of variation $\sigma_\Phi/\Phi_s = 12.8\%$, which is lower than the relative error $\epsilon = 25\%$ by a factor 2.

Another approach involves replicating the initial run to refine the estimate $\Phi_s$. The average of the eight runs provides a mean rate $\Phi_s = 0.95$ grain/s for $\Delta t = 10$ s, and
Figure 2. (a) Illustration of the virtual experiment: particles move randomly at velocity $u_p$ and cross the control surface $S$. (b) Time variations in the number of particles $N(t)$ that have crossed the control surface $S$ until time $t$. Here we simulated eight paths of the Poisson process $N(t)$ with rate $\nu = 1$ grains/s and a sampling rate $\delta t = 5$ ms (thus generating $M = 4000$ values of $N$ for each path).

$\Phi_s = 1.02$ grain/s for $\Delta t = 20$ s, with the relative error thus dropping to 2%–5%. This shows that by combining time and run averages, we can reduce uncertainties when measuring bedload transport. Run averaging is close to ensemble averaging $\langle \bar{\Phi}_s \rangle = \lim_{n \to \infty} \sum_{i=1}^{n} N/\Delta t$, which is the tool we will be using in this paper. At this stage of the example, one might doubt that much progress has been made if, in practice, one has to reiterate measurements instead of extending the sampling duration $\Delta t$. This is where theory comes in.

We will show that uncertainties (expressed here in terms of ensemble-variance $\text{var} \bar{\Phi}_s$) vary as $\text{var} \bar{\Phi}_s = K/\Delta t$. The proportionality factor $K$ depends on the measurement protocol and transport stage. When measuring low transport rates, $K$ is equal or close to the mean flux $\Phi_s$. If we go back to the example in Fig. 2 and consider path AB again, we measure $\bar{\Phi}_s = 15/20 = 0.75$ grains/s, thus deducing that the ensemble variance is approximated by $\text{var} \bar{\Phi}_s = \bar{\Phi}_s/\Delta t = 0.0375$ grains$^2$/s$^2$ and expecting the actual rate to fall within or close to the range $\bar{\Phi}_s \pm \sqrt{\text{var} \bar{\Phi}_s} = [0.56, 0.94]$ grains/s. The ensemble-averaged variance $\text{var} \bar{\Phi}_s$ thus provides a better estimate of the uncertainties of $\bar{\Phi}_s$ than the sample mean.

We have been able to estimate the ensemble-averaged variance from a single path because we have taken advantage of our knowledge of sediment transport: it behaves like a Markov process at low transport rates. At higher transport rates, the assumption of a Markov process breaks down, but our statistical approach is still possible. It requires more statistical information about $\Phi_s$ to implement renewal theory and determine the value of $K$. High-resolution data were needed for this. Admittedly, replicating measurements is usually difficult (and often impossible), but we will see that statistical techniques such as bootstrapping allow us to estimate the ensemble mean and variance. In the absence of high-resolution data, applying the central limit theorem provides an estimate of $K$.
2 Theory

2.1 Definitions and Notation

The present paper uses two different definitions of the bedload transport rate $Q_s$ from among the numerous forms currently in use (Ancey, 2010; Furbish et al., 2012; Ballio et al., 2014). We have tailored these definitions to the specific analysis developed in this paper (see the end of this section for how these definitions can be generalized in real-world applications). First, for most theoretical developments, we will express $Q_s$ in grains/s. Second, we will consider a flow per unit width. Although many of the equations presented seem to have been formulated for a two-dimensional problem, the third spatial dimension should not be forgotten. For this reason, we will refer to “control volume” even though this volume is two-dimensional in Fig. 3 (the same holds for the control surface and streambed area below).

- Flux of particles across a control surface (see Fig. 3). We count the number of particles crossing the control surface $S$ during the sampling duration $\Delta t$:

$$\Phi_s(\Delta t|t) = \frac{1}{\Delta t} \int_t^{t+\Delta t} \phi_s(\tau)d\tau,$$

where $\phi_s(\tau)d\tau$ gives the number of particles intersecting the control surface $S$ between time $\tau$ and $\tau+d\tau$. Thereafter, we will mostly work with Markov processes that describe weak sediment transport: in such cases, the probability of observing two particles crossing the control surface at the same time drops to zero, and $\phi_s d\tau$ can either be zero (no particle crossing $S$) or unity (one particle crossing $S$). The arrival of individual particles will be described as a Poisson process in §2.3.

When this assumption breaks down at sufficiently high transport rates, $\phi_s$ can take any integer value, and we describe particle arrival as a renewal process (see Appendix B). Equation (1) is probably the most natural definition in fluid mechanics because particle transport rates usually reflect mass fluxes. Indeed, it is equivalent to the definition used in continuum mechanics $Q_s = \int_S H(x)u_p(x,t)\cdot n dS$ (where $H(x)$ is unity when point $x$ is occupied by a particle and zero otherwise, $u_p$ is the particle velocity field at $x$, and $n$ is the outward-oriented normal to $S$).

- Volume-averaged particle transport rate. By averaging particle motion through a control volume, we relate the bedload transport rate to the volume-averaged particle velocity $U_p = \sum_{i=1}^N u_{p,i}$ (where $u_{p,i}$ is the instantaneous particle velocity) and the number of moving particles $N$ (Ancey & Heyman, 2014):

$$q_s = \frac{N}{A} U_p,$$

where $N/A$ is called the particle activity (that is, the number of moving particles per unit of streambed area $A$) (Furbish et al., 2012). Counting the number of moving particles and determining their mean velocity leads to the instantaneous volume-averaged transport rate $q_s$. We can calculate its time average:

$$\bar{q}_s(\Delta t|t) = \frac{1}{\Delta t} \int_t^{t+\Delta t} q_s(\tau)d\tau,$$

where $\Delta t$ is the sampling duration. If we assume that particles move at a constant velocity, then computing the bedload transport rate involves determining the number of moving particles $N$. Calculating the time-averaged bedload transport rate $\bar{q}_s$ is tantamount to calculating the time integral of $N(t)$. This is what we will do below by using some general results for Markov processes (see Appendix A) and by applying renewal theory (see Appendix B).

We introduce three averages:
Figure 3. Notation and illustration of the exchange processes considered. The water flow transports particles. The mean particle flux is $\nu_{in}$. The number of moving particles $N$ in the control volume $V$ varies as a result of particles entering and leaving the volume and being entrained or deposited on the bed. Bed particles can be dislodged by the water drag (there is a probability $\lambda dt$ that this occurs within a short time interval $dt$) or because of interactions with moving particles (as there are $N$ moving particles, the resulting probability of entrainment is $\mu N dt$).

- The ensemble average $\langle f \rangle$ of the random quantity $f$ is obtained by averaging $f$ over all possible realizations (Herczynski & Pienkowska, 1980; Lhuillier, 1992; Drew & Passman, 1999)—the electronic supplement to (Aucey & Heyman, 2014) provides a more formal introduction to this average. If $f$ depends on time $t$, then $\langle f \rangle$ is also a function of $t$. We denote the steady-state ensemble-averaged value of $f$ by $\langle f \rangle_{ss}$, which is the value reached by $\langle f \rangle$ at sufficiently long time intervals for the initial condition’s influence to be negligible.

- The time average $\bar{f}$ is defined as the time integral over the sampling duration $\Delta t$:

$$\bar{f}(\Delta t|t) = \frac{1}{\Delta t} \int_{t}^{t+\Delta t} f(\tau) d\tau. \quad (4)$$

- We can combine both averages to produce the double-averaged (time- and ensemble-averaged) quantity $\langle f \rangle$.

To keep the notation less cluttered, we did not introduce any special symbol to refer to the volume-average underpinning the derivation of Eq. (2). When sediment transport involves grains of the same size, we can readily convert transport rates expressed in grains/s into rates expressed in kg/s or m$^3$/s. When considering grains of different sizes, the definitions (1) and Eq. (3) can be generalized by partitioning the grain size-distribution into classes and computing particle transport rates for each class.

2.2 Assumptions

We consider a one-dimensional system under steady-state conditions, corresponding to a narrow, tilted flume with a constant feed rate at its inlet (the flow geometry that will be investigated experimentally in § 4). Under these flow conditions, particles move in the same direction as the water flow, and cross-stream diffusion—observed in wider flumes (Seizilles et al., 2014)—can be neglected. The influence of bedforms on flow dynamics and bedload transport is supposed to be negligible, and thus the bed is in equilibrium with no significant elevation variation along its interface with the flow (neither aggradation nor degradation). Particles move at velocity $u_p$, which may fluctuate over time. The mean particle velocity is denoted by $\bar{u}_p$. Velocity fluctuations are assumed to be Gaussian, with standard deviation $\sigma_u$. The probability $P_u$ of observing a given value
The central element of our theoretical development is the calculation of the number $N$ of particles crossing a control surface or contained in a control volume. To that end, we use the stochastic bedload transport model proposed by Ancey et al. (2008). The number of moving particles $N$ varies with time as a result of (i) deposition and (ii) entrainment. Particles come to rest at a rate $\sigma [1/s]$. The deposition rate $D$ is thus $D = \sigma N$ [grains/s]. We introduce two forms of entrainment:

- **Individual entrainment** at a rate $\lambda$ [grains/s], which reflects the classic mechanism of entrainment by the water flow.
- **Collective entrainment** at a rate $\mu [1/s]$, which takes particle–particle interactions into account.

The number of particles entrained per unit time is thus: $E = \lambda + \mu N$, where $E$ is the **entrainment rate** [grains/s]. To accurately count particles, the system’s dimensions must be specified. We consider a control window $V$ of length $L$. The window’s downstream (or equivalently, upstream) face is the control surface $S$ (see Fig. 3).

We assume that the particle flux can be described as a Markovian process. This implies that the probability of observing $N$ moving particles depends only on recent flux history (there is no memory effect). Differently put, the probability $P$ that one particle crosses the control surface $S$ during the time interval $[t, t+\delta t]$ is $P = \nu_{in}\delta t$ (where $\nu_{in}$ is the feed rate), and thus that probability depends solely on the time interval $\delta t$. When $\delta t$ is infinitesimally small, then only one particle can cross the control surface (Markovian process theory cannot deal with multiple events). Equivalently, it can be shown that the waiting time $\tau$ between two particle-arrivals is exponentially distributed, with parameter $\Lambda = \nu_{in}$ [grains/s] (or equivalent with a mean waiting time $t_w = \nu_{in}^{-1}$):

$$ P_{\tau}(\tau) = \Lambda \exp(-\Lambda \tau). \quad (6) $$

### 2.3 Time-Averaged Particle Flux

With these assumptions, we deduce immediately that the number of particles that have crossed the control surface $S$ up to time $t$ is a Poisson process (Cox & Miller, 1965; Gillespie, 1992). It is straightforward to show that the ensemble average and variance are (Gillespie, 1992):

$$ \langle N \rangle = \Lambda t \quad \text{and} \quad \text{var} \ N = \Lambda t. \quad (7) $$

Using Eq. (1), we then deduce that the mean (double-averaged) flux is

$$ \langle \Phi_s \rangle / (\Delta t | t) = \frac{\langle N \rangle (t + \Delta t) - \langle N \rangle (t)}{\Delta t} = \Lambda, \quad (8) $$

regardless of $\Delta t$, whereas the variance is

$$ \text{var} \ \Phi_s (\Delta t | t) = \frac{\Lambda}{\Delta t}. \quad (9) $$

Interestingly, we note that according to the Poisson process, the fluctuation strength varies linearly with the mean particle flux $\Lambda$ and is inversely proportional to the sampling duration $\Delta t$. 

\[ -8 - \]
2.4 Volume-Averaged Bedload Transport Rate for \( \sigma_u = 0 \)

Let us first consider the simplest case, in which the particle velocity fluctuations are negligible relative to their mean velocity \( \bar{u}_p \) (that is, we assume that \( \sigma_u = 0 \)). The number \( N \) of moving particles in the control window \( V \) can be described as a birth–death immigration–emigration Markov process (Cox & Miller, 1965): entrainment and deposition correspond to birth and death, respectively, whereas immigration and emigration reflect the arrival and departure of particles. The immigration rate is \( \nu_{in} \), and the emigration rate is

\[
\nu_{out} = \frac{\bar{u}_p}{L},
\]

where \( L \) is the length of the control window. Under steady-state conditions, the probability of observing \( N \) particles in the control volume \( V \) can be calculated analytically. Here we summarize the main results and refer the reader to an earlier publication for the proofs (Ancey et al., 2008).

When the collective entrainment rate \( \mu \) is non-zero, this probability is the negative binomial distribution:

\[
P_n(n) = \text{prob}(N = n) = \left( \begin{array}{c} q + n - 1 \\ q - 1 \end{array} \right) p^n (1 - p)^n
\]

with parameters \( p \) and \( q \):

\[
q = \frac{\lambda + \nu_{in}}{\mu} \quad \text{and} \quad p = 1 - \frac{\mu}{\nu_{out} + \sigma - \mu}
\]

The autocorrelation function of the time series \( N(t) \) is

\[
\rho(\tau|t) = \frac{\text{cov}(N(t), N(t + \tau))}{\text{var} N(t)} = e^{-\tau/t_c},
\]

where \( t_c = 1/(\nu_{out} + \sigma - \mu) \) is the autocorrelation time. Under steady-state conditions, the ensemble average and mean of \( N \) are thus

\[
\langle N \rangle_{ss} = \frac{\lambda + \nu_{in}}{\nu_{out} + \sigma - \mu} \quad \text{and} \quad \text{var}_{ss} N = \frac{(\lambda + \nu_{in}) (\nu_{out} + \sigma)}{(\nu_{out} + \sigma - \mu)^2}.
\]

The instantaneous bedload transport in the control volume \( V \) is given by Eq. (2). As we assume that particles move at constant velocity \( \bar{u}_p \), then all the \( q \) fluctuations result solely from the time variations in the number of moving particles \( N \). Combining Eqs. (2) and (14), we find that under steady-state conditions, the ensemble-average bed transport rate is

\[
\langle q_s \rangle_{ss} = \frac{\bar{u}_p}{L} \langle N \rangle_{ss} = \frac{\lambda + \nu_{in}}{\nu_{out} + \sigma - \mu} \frac{\bar{u}_p}{L}.
\]

Because under steady-state conditions we have \( \bar{u}_p \langle N \rangle_{ss}/L = \nu_{in} = \Lambda \), the steady-state mean transport rate (15) matches the mean particle flux (8). The variance takes a more complicated form:

\[
\text{var}_{ss} q_s = \frac{\bar{u}_p^2}{L^2} \text{var}_{ss} N = \frac{\bar{u}_p^2 (\lambda + \nu_{in}) (\nu_{out} + \sigma)}{L^2} \frac{(\nu_{out} + \sigma - \mu)^2}{(\nu_{out} + \sigma - \mu)^2}.
\]

Calculating the double-averaged bedload transport rate \( \langle \dot{q}_s \rangle \) requires more work. First, we can derive the governing equation specific for \( \langle N(t) \rangle \), its higher moments, and its time integral \( \int N(t) \, dt \) (see Appendix A for the mathematical detail). By using Eq. (A19) and assuming that particles were initially still \( (N_0 = N(t = 0) = 0) \) in the control volume, we find that

\[
\langle \dot{q}_s \rangle (\Delta t|t) = \frac{\bar{u}_p}{L} \frac{\lambda + \nu_{in}}{\nu_{out} + \sigma - \mu} \left( 1 - \frac{t_c}{\Delta t} \left( 1 - e^{-\Delta t/t_c} \right) \right),
\]

where \( t_c = 1/(\nu_{out} + \sigma - \mu) \) is the autocorrelation time.
which tends to \( \langle q_s \rangle_{ss} \) when the sampling duration \( \Delta t \) is sufficiently long relative to the autocorrelation duration \( t_c \). Asymptotically, the variance is deduced by taking the limit \( \Delta t \gg t_c \) in Eq. (A22):

\[
\text{var} \bar{q}_s(\Delta t|t) = \frac{\bar{u}^2_p}{L^2 \Delta t} \left( \frac{\lambda + \nu_{in}(\nu_{out} + \sigma)}{\nu_{out} + \sigma - \mu} \right)^2 = \frac{\bar{u}^2_p}{L^2 \text{var}_{ss}} N t_c \frac{t_c}{\Delta t}. \tag{18}
\]

Contrary to the average (17), the double-averaged variance does not converge to the steady-state ensemble-averaged variance (16) when \( \Delta t \gg t_c \). We also note that, contrary to the particle flux, the fluctuation strength depends on many parameters and does not seem to be trivially related to the mean bedload transport rate. The particle flux, however, is inversely proportional to the sampling duration. We can intuitively estimate that the proportionality factor \( \bar{u}^2_p \frac{\text{var}_{ss}}{L^2} N t_c / L^2 \) in Eq. (18) should be close to \( \Lambda \). As shown in § 4, this link between \( \bar{u}^2_p \frac{\text{var}_{ss}}{L^2} N t_c / L^2 \) and \( \Lambda \) was observed experimentally, but we have no theoretical argument with which to rigorously demonstrate it.

### 2.5 Volume-Averaged Bedload Transport Rate for \( \sigma_u > 0 \)

Calculations become more involved when considering velocity fluctuations, but they are still tractable analytically. We assume that the number of moving particles is distributed according to a negative binomial distribution (11), whose parameters are given by Eq. (12). We also assume that the instantaneous particle velocity \( u_{p,i} \) is normally distributed (see Eq. (5)). We assume that the two marginal probabilities \( P_n \) and \( P_u \) fully describe the process or, to put it differently, there is no correlation between \( N \) and \( u_{p,i} \).

We define \( U \) as the sum of the particle velocities:

\[
U = \sum_{i=1}^{N} u_{p,i}. \tag{19}
\]

As the volume-averaged particle transport rate in the control window \( V \) is \( q_s = U/L \), the probability density function of \( q_s \) is related to that of \( U \):

\[
P_{q_s} = LP_U(Lq_s). \tag{20}
\]

The probability \( P_U \) of \( U \) is obtained by summing the elementary probabilities of observing \( k \) particles, in the control window, whose velocity sum equals \( U \):

\[
P_U = \sum_{k=1}^{\infty} P_n(k)P_k(U), \tag{21}
\]

where \( P_k \) denotes the probability of observing that the velocity sum is equal to \( U \). As the sum of normally distributed random variables is also normally distributed, \( P_k \) is the normal distribution \( \mathcal{N} \), with mean \( k\bar{u}_p \) and standard deviation \( \sqrt{k\sigma_u} \). We then deduce:

\[
P_{q_s} = LP_U(Lq_s) = \sum_{k=1}^{\infty} P_n(k)P_k(Lq_s)
= \sum_{k=1}^{\infty} L \left( \frac{q+n-1}{q-1} \right) p^q (1-p)^n \mathcal{N}(k\bar{u}_p/L, \sqrt{k\sigma_u}/L)(Lq_s). \tag{22}
\]

It is then straightforward to infer the mean and variance of \( q_s \) even though there is no closed-form expression for the probability \( P_{q_s} \):

\[
\langle q_s \rangle = \int \limits_{\mathbb{R}} q_s P_{q_s} \, dq_s = \frac{N_{ss}}{L} \bar{u}_p, \tag{23}
\]

\[
\text{var} q_s = \int \limits_{\mathbb{R}} (q_s - \langle q_s \rangle)^2 P_{q_s} \, dq_s = \text{var}_{ss} N \frac{\bar{u}^2_p + p\sigma_u^2}{L^2}. \tag{24}
\]
When $\sigma_n = 0$, we retrieve the variance given by Eq. (18). In Appendix C, we show that if we select an exponential distribution for the particle velocities, then there is no change in the ensemble average and only a slight change in the ensemble variance.

If we assume that events (particle velocity and particle number) are independent, then we can generalize the variance equation (18) to take velocity fluctuations into account in the double-averaged variance by following the same reasoning as that used for deriving Eq. (18):  

$$\text{var} \bar{q}_s(\Delta t|t) = \frac{\bar{u}_m^2 + p \text{var} u (\lambda + v_{in})(v_{out} + \sigma)}{L^2 \Delta t} \cdot (v_{out} + \sigma - \mu)^3 = \text{var}_{ss} N \frac{\bar{u}_m^2 + p \text{var} u \cdot t_c}{L^2 \Delta t}. \quad (25)$$

### 2.6 Summary of Results

When we considered that a steady-state system in which the particle flux across a vertical control surface $S$ was a Poisson process with rate $\Lambda$, we found that the double-averaged particle flux (8) was $\Lambda$, independently of the sampling duration $\Delta t$. Under steady-state conditions, mass conservation imposes that $\nu_{in} = \nu_{out}(N)_{ss}$ in the control window $V$. Using Eq. (10), we then deduced that the double-averaged bedload transport rate (15) or (23) was also $\Lambda$ in the limit $\Delta t \gg t_c$. We thus concluded that, on average, both transport rate definitions provided identical results:  

$$\langle \bar{q}_s \rangle = \langle \Phi_s \rangle. \quad (26)$$

These results, however, differed with regards to the variance of $\bar{q}_s$ or $\Phi_s$: the variance of the double-averaged flux $\langle \Phi_s \rangle$ varied as $\Lambda/\Delta t$, whereas the variance of the double-averaged transport rate $\langle \bar{q}_s \rangle$ varied like $\nu_{out}\text{var}_{ss} N \Delta t$ given by Eq. (18) (or like Eq. (25) if velocity fluctuations were taken into account). The fact that the variance varied like $1/\Delta t$ comes as no surprise because the central limit theorem states that the scaled sum $S_n$ of $n$ independent and identically distributed random variables $Y_i$ (with finite mean $\mu_y$ and standard deviation $\sigma_y$) converges in distribution to a normal distribution with mean 0 and variance 1 (Grimmett & Stirzaker, 2008):  

$$\frac{S_n - n\mu_y}{\sqrt{n}\sigma_y} \xrightarrow{d} \mathcal{N}(0, 1). \quad (27)$$

If we apply the central limit theorem to a long time-series $(t_i = i\delta t, y_i)$, where $1 \leq i \leq n$ and where $\delta t$ denotes the time interval between two measurements, with $y_i = Q_i$, the transport rate at time $t_i$, then the time-averaged bedload transport rate is $\bar{q}_s(t_n) = S_n\delta t/\Delta t$. Furthermore, when $n$ is large, we have: $S_n \rightarrow n\mu_y$ and var $S_n \rightarrow n\sigma_y^2$, thus $Q_s \rightarrow \mu_y$ and var $Q_s \rightarrow \sigma_y^2\delta t/\Delta t$ because $n \propto \Delta t/\delta t$. Asymptotically, for any sample that satisfies the application conditions of the central limit theorem, then the relation $\text{var} \bar{q}_s \propto \Delta t^{-1}$ also holds true. The difference between this scaling and Eqs. (18) and (9) is that in the Markovian case, the variation $\text{var} \bar{q}_s \propto \Delta t^{-1}$ holds exactly for any sampling duration $\Delta t$. Furthermore, in the case of a Poisson process, the steady-state variance in Eq. (9) is entirely controlled by the mean particle flux $\Lambda$, and there is no need to introduce another parameter $\sigma_y$ to find its value.

### 2.7 Protocol for Measuring the Sediment Transport Rate and its Variance

In Eqs. (8) and (15), the transport rates $\langle \bar{q}_s \rangle$ and $\langle \Phi_s \rangle$ are based on ensemble averages. The problem is that it is difficult to calculate ensemble averages directly in experiments (unless many runs of the same experiment can be made). There is, however, a fairly simple technique that mimics the ensemble average and makes it possible to deduce the sample mean and variance with high precision: the bootstrap method (Davison
& Hinkley, 1997). Like the jackknife, this is a resampling technique, which involves repeatedly drawing random subsamples from a single original sample and generating new samples with similar statistical properties to those exhibited by the original one (Davison & Hinkley, 1997). We assume a time series \( (t_i = i \delta t, y_i) \) \( 1 \leq i \leq n \), where the variables \( y_i \) are independent and identically distributed random values drawn from an underlying distribution \( F \). We assume that we do not know \( F \), but we can get an empirical estimate \( \hat{F} \) by using the sample \( (y_1, y_2, \ldots, y_n) \). We can then draw \( M \) samples of \( n \) values from \( \hat{F} \). We use these \( M \) samples to compute the sample mean and variance.

Thus, the key point is starting with a sample of independent and identically distributed data. The tests are detailed in § 4. Here, we would like to highlight a simple test of stationarity, which turns out to be robust and useful in a variety of settings. Because of the existence of fluctuations in the \( q_i \) time series, it may be difficult to distinguish between stationarity, weak stationarity, and absence of stationarity. Below, we plot the cumulative amount of sediment \( S_n = \sum_{i=1}^{n} y_i \Delta t \) (here \( y_i \) denotes the particle flux \( \Phi_i \) or volume-averaged transport rate \( q_i \)) as a function of time (see Fig. 4 for an example). If the steps \( (t_n, S_n) \) come close to a straight line of slope \( \Lambda \), then the process is probably stationary: the mean flux will be close to \( \hat{\Lambda} \). Should only some groups of intervals \( (t_n, S_n) \) form segments of the line, then the process is weakly stationary. These groups can then be used to identify the periods during which the process was reasonably close to a stationary process. If there is no good match between these groups and the line representing steady state, the protocol cannot be applied.

Our protocol for defining the mean bedload transport rate and its variance is the following:

- If we can acquire data at a sufficiently high frequency, then we resolve the times at which particles cross the control surface \( S \) or move within the control window \( V \). We can then determine the waiting time between particle arrivals, or measure particle velocity. This is the ideal case against which we will test the theory outlined in this section. Although an emphasis is placed on Markovian processes, particles may behave differently; notably, many particles cross the control surface \( S \) within a short time-interval (“many” here means that the number of particles crossing the surface cannot be described using the Poisson law). Appendix B shows how renewal theory can be used in these cases.
- In the opposite case, when the data acquisition rate is low (typically below 1 Hz), we can still apply the protocol, but it will be difficult to verify whether the theory described above captures the flux behavior well. The central limit theorem is, however, sufficient to deduce the key information of the bedload transport rate’s mean and variance. There is, of course, no free lunch. The price paid for low-frequency measurements is that the fluctuation strength is independent of the mean particle flux. Naturally, this does not cause trouble when working under steady-state conditions (one can estimate \( \sigma_y \)), but it becomes more problematic under time-dependent flow conditions.

The steps are the following:

1. Plot the cumulated amount of sediment on a graph \( (t_n, S_n = \delta t \sum_{i=1}^{n} y_i) \) and identify the periods \( T \) during which the steps are close to a straight line of slope \( \Lambda \), that is, the period during which the process was stationary or quasi-stationary. The slope \( \Lambda \) represents the mean transport rate over time \( T \), and \( S_n \) is a time discretization of \( \int y(t)dt \).
2. From this period \( T \), we can extract a sample \( (t_i, y_i) \) involving \( n_T \sim T/\delta t \) values. Because we need to handle independent and identically distributed random variables \( y_i \), we must check that this assumption is satisfied. In practice, if one measures volume-averaged transport rates \( q_i \), the assumption of independent and
identically distributed data implies that the time interval $\delta t$ should be larger than
the autocorrelation time, otherwise neighboring values would be correlated. The
“training” sample $(t_i, y_i)_{1 \leq i \leq n_T}$ is used to generate random samples, using the boot-
strap resampling technique (Davison & Hinkley, 1997).

3. We can estimate the variance of $\langle \hat{y} \rangle (\Delta t)$ by generating $M$ samples (typically $M =
100$ is recommended) of size $n_r = \Delta t/\delta t$ from the training sample (e.g., see Davison
and Hinkley (1997) on how to use the bootstrap method) and estimating the vari-
ance $\text{var} \hat{y}$ of this group.

4. When plotted as a function of $\Delta t$, the empirical variance $\text{var} \hat{y}(\Delta t)$ should lie on the
curve $\hat{\Lambda}/\Delta t$, by virtue of Eqs. (18) or (9), if the data were collected at a sufficiently
high frequency. If they were not, we can use the central limit theorem (27), and
the data should be close to the curve $\sigma_y \delta t/\Delta t$.

5. The empirical variance curve $\text{var} \hat{y}(\Delta t)$ makes it possible to specify the accuracy
associated with the measurement of the double-averaged transport rate over the
duration $\Delta t$ or, reciprocally, to select the value of $\Delta t$ that corresponds to the de-
sired accuracy (i.e., the prescribed $\sigma_y$).

3 Experimental Procedure

3.1 Experimental Set-up

The flume used was 2.5 m long, 40 mm wide, and tilted at an angle of 1.55° from
the horizontal. Water discharge at the flume inlet was set to $Q_w = 0.2$ L/s, and flow
depth was 1.1 cm (the hydraulic radius was $R_h = 71$ mm). The flow was supercriti-
cal (with a Froude number of 1.1). This choice of the flow regime was driven by our de-
sire to approach the flow conditions found in mountain streams (the subject of our re-
search) and to limit the effects of sidewall friction on flow turbulence. Well-sorted gravel
(mean diameter $d_{50} = 3$ mm, density $\rho_p = 2550$ kg/m$^3$) was layered along the flume
bottom to a thickness of 4 cm, and the same gravel was used to feed the flume at a feed
rate of $10.3 \pm 0.5$ grains/s. The Shields number was $\Theta = \rho g R_h/((\rho_p - \rho) d_{50} = 0.043$ (if
we use the empirical equation for gravel beds proposed by Recking (2013), we obtain $\Theta =
0.045$). We designed a specific system to feed the flume with sediment (see Supporting
Information for photographs), bounded by two constraints: the feed rate had to be low
(a few grains per second) and the particle flux had to be as close to a Poisson process
as possible. Gravel was initially contained in a hopper whose opening controlled the in-
flow rate. The particles fell onto a slowly rotating cylinder ($\Omega = 0.4$ rad/s) whose sur-
face was covered with sandpaper. A vertical brush prevented grains from stacking and
generating avalanches. After the cylinder had rotated by a certain angle, any grain stuck
to the rough cylinder exterior was dislodged and fell into the flume. The grains fell onto
a smooth white board, slipped down it while being filmed by a high-speed camera, and
then arrived at the flume inlet, where they were entrained by the flow. Although the match
was not perfect, the particle flux at the flume inlet was very close to a Poisson process.

3.2 Image Processing and Tracking

Images were collected at 250 frames per second using a high-speed Basler A504k
camera equipped with a Nikkor-S 1:1.4 $f = 50$ mm lens, at a resolution of 624 $\times$ 300
pixels (with the scale 1 px = 0.133 mm). A 35-cm long transparent plastic plate was placed
above the water surface to prevent reflections and image distortion created by free sur-
face waves. Images were taken from vertically above this plate. This set-up caused a lo-
cal flow disturbance whose effects were negligible on the flow portion under the plate,
although we presume that it exacerbated bedforms downstream of the plate. Three LED
spotlights illuminated the control window homogeneously. The experimental run lasted
22 min, and initial images were removed to extract a sequence of 20 min.
The raw images were processed by subtracting their background image, defined as
the median of the 20 previous frames. This preliminary step enabled us to highlight mov-
ing particles and discard jiggling particles which were not being transported by the flow.
Particle tracking was based on a procedure available from the TrackMate-ImageJ numer-
cal framework (Tinevez et al., 2017). First, spot detection was carried out using a Lapla-
cian of the Gaussian detector and considering an estimate of the mean grain size in the
images as the detector size parameter. Second, in the particle linking step, we modified
and used the Linear Assignment Problem (LAP) tracker initially proposed by Jaqaman
et al. (2008): we modified the linking cost function so that it accounted for the prefer-
dential direction of particle displacement (downstream in our case). The gap closing op-
tion was allowed over two time steps. Moreover, spots and trajectories were filtered to
reduce tracking errors, mostly caused by moving bubbles trapped at the interface between
the transparent plate and the water flow. After the spot detection step, we filtered spots
by considering their properties, which enabled us to identify spots associated with mov-
ing bubbles. We rejected spots characterized by an estimated diameter smaller than 7
px and/or by a maximum pixel intensity higher than 160 (over 255). Among the trajec-
tories reconstructed using the particle linking procedure, we discarded those composed
of fewer than 4 spots in order to remove short tracklets caused by bubbles and improper
particle linking. A validation test of this tracking method was conducted, and it is pre-
sented in the Supporting Information.

Finally, the resulting tracks were analyzed to calculate the variables of interest for
the present study: we emphasized the time series \( t_i, N_i \) of the number of moving par-
ticles, the distribution of the particle velocity \( u_p \) (averaged over all particle paths for each
image), and the time series of the particle fluxes in the downstream section of the con-
trol window \( \Phi_s(t) \). We considered three control windows of different streamwise lengths
\( L = 17.5 \text{ mm}, 35 \text{ mm}, \text{ and } 70 \text{ mm} \), all located in the same section and starting 1.32 m
from the flume inlet \( x = 0 \). We present only results obtained with the longest win-
dow \( L = 70 \text{ mm} \). See the Supporting Information for further data on \( L \)'s influence on
the results (which was found to be small, on average).

4 Results

This section addresses the following points. First, we compare the various predic-
tions of the Markovian theory developed in § 2 against high-resolution experimental data.
Second, we test the protocol proposed in § 2.7. Third, to estimate whether this proto-
col has potential, we evaluate its performance under more complicated flow conditions:
because bedforms developed downstream of the plate and thus influenced the bedload
transport rate, we look more closely at the data acquired at the flume outlet. Before ad-
dressing each of these points, we adjust the model parameters \( \lambda, \mu, \sigma, \nu_{\text{out}}, \bar{u}_p \), and
\( \sigma_u \) from the time series \( t_i = i \delta t, N_i, u_i \), where \( \delta t = 4 \text{ ms} \) is the time interval between
two images, and \( N_i \) is the number of moving particles in the control volume. The inflow
rate \( \nu_{\text{in}} = 10.3 \text{ grains/s} \) was imposed experimentally at the flume inlet.

4.1 Parameter Estimation

Of five model parameters—entrainment parameters \( \lambda \) and \( \mu \), deposition rate \( \sigma \),
and flux parameters \( \nu_{\text{out}} \) and \( \nu_{\text{in}} \)—four are unknown and \( \nu_{\text{in}} = 9.98 \text{ grains/s} \) was set
experimentally (taking the value measured in the control window rather than the one
fixed at the flume inlet). We only need to select four relationships to determine the un-
knowns, but at least five equations are available:

1. Bed equilibrium

\[
\sigma \langle N \rangle_{ss} = \mu \langle N \rangle_{ss} + \lambda.
\] (28)
Table 1. Empirical and theoretical probabilities of observing $k$ particles crossing the control surface $S$ within the time interval $\delta t = 4$ ms.

2. Flux steadiness

\[ \nu_{in} = \nu_{out} \langle N \rangle_{ss}. \] (29)

3. Condition on the average $N$ value

\[ \langle N \rangle_{ss} = \frac{\beta}{\alpha} = \frac{\lambda + \nu_{in}}{\nu_{out} + \sigma - \mu}. \] (30)

4. Condition on the $N$ variance

\[ \text{var}_{ss} N = \frac{(\lambda + \nu_{in})(\nu_{out} + \sigma)}{(\nu_{out} + \sigma - \mu)^2}. \] (31)

5. Condition on the autocorrelation time

\[ \nu_{out} + \sigma - \mu = t_c^{-1}. \] (32)

The autocorrelation time was $t_c = 221$ ms (see Fig. 6(b)). We set $\nu_{out}$ from Eq. (29): $\nu_{out} = \nu_{in}/\langle N \rangle_{ss} = 1.88$ 1/s. We solved Eqs. (30), (31), and (32) for $\lambda$, $\mu$, and $\sigma$. We found $\lambda = 14.77$ grains/s, $\mu = 4.98$ 1/s, and $\sigma = 7.68$ 1/s. Furthermore, we inferred from the processed images that the mean particle velocity was $\bar{u}_p = 13.41$ cm/s and its standard deviation was $\sigma_u = 3.24$ cm/s. Note the value $\nu_{out} = 1.82$ 1/s was 5% below the theoretical value $\nu_{out} = \bar{u}_p/L = 1.91$ 1/s. Equation (28) was used to test whether the fitted values were consistent with the assumption of bed equilibrium.

4.2 Particle Flux

We begin our analysis with the particle flux across the control surface $S$ located at the control volume’s downstream end. Grains crossed the control surface at a mean rate $\bar{\Lambda} = N_{tot}/T_{exp} = \nu_{in} = 9.98$ grains/s ($N_{tot} = 11.974$ was the total number of grains to have crossed $S$ over the run duration $T_{exp} = 1200$ s). As shown by Fig. 4(a), the particle flux was almost stationary, even though the time variations in $\Phi_s$ exhibited wide fluctuations over short timescales (see Fig. 8). The mean number of particles crossing the control surface $S$ within $\delta t = 4$ ms was $\bar{N} = 0.04127$, whereas the variance was $\text{var} N = 0.04130$. The 0.07% deviation between these two values shows that the assumption of a Poisson process was realistic. Table 1 shows that the Poisson model properly predicts the number of particles crossing the window per time interval $\delta t$. The error for $k = 3$ particles is likely to have resulted from the sample’s finite size (only three occurrences in 1200 s). The partial autocorrelation function was close to 1 for a lag of 1, then vanishingly small for lags larger than 1, as expected for a Poisson process.

Stationary jump processes are fully characterized by the probability of observing the process in a given state and by the waiting times $\tau$ between two jumps (Gillespie, 1992). Although Table 1 and Fig. 4(a) support the idea of a Poisson process, examining the waiting-time distribution tells us a different story: Fig. 4(b) shows the empirical probability density function of waiting times and their exponential distribution (6) (with rate $\bar{\lambda} = 9.77$ s$^{-1}$ adjusted on the waiting time sample using the method of moments). Over short periods, there was a fairly good match between the empirical and
Figure 4. (a) Variation over time of the cumulative number of particles crossing the control surface $\sum_0^t \phi_s(\tau) \delta t$. The red line represents the cumulative number of particles $\sum \phi_s \delta t = \hat{\Lambda} t$ with $\hat{\Lambda} = \nu_m = 9.98$ grains/s. (b) Waiting times for the flux at the control window’s downstream end $S$. The solid red line represents the exponential distribution (6) with rate $\hat{\Lambda} = 9.77$ s$^{-1}$ adjusted on the waiting time sample using the method of moments. The dashed black line represents the hyper-exponential distribution (33) fitted to the data using the method of moments. The dotted blue line represents the hyper-exponential distribution (35) adjusted on the flume inlet’s data. The light blue dots show the empirical probabilities.
theoretical distributions, but for periods longer than 400 ms, deviation from the exponential distribution was marked. The sample’s coefficient of variation was $\sigma_{\bar{r}}/\bar{r} = 1.21$ (standard deviation $\sigma_{\tau} = \sqrt{\text{var} \bar{\tau}} = 124$ ms, mean $\bar{\tau} = 102$ ms), thus higher than unity. This confirmed that waiting times were not strictly exponentially distributed. To better describe the probability distribution of waiting times, we can adjust a two-parameter hyper-exponential distribution, whose density function is:

$$p(\tau) = \alpha_1 \lambda_1 \exp(-\lambda_1 \tau) + \alpha_2 \lambda_2 \exp(-\lambda_2 \tau),$$  \hspace{1cm} (33)

where $\alpha_1$ and $\alpha_2$ are mixture parameters satisfying $\alpha_1 + \alpha_2 = 1$, whereas $\lambda_1$ and $\lambda_2$ are two rates. Using the method of maximum likelihood, we found:

$$\alpha_1 = 0.13, \lambda_1 = 4.33 \text{ s}^{-1}, \alpha_2 = 0.87, \text{ and } \lambda_2 = 12.04 \text{ s}^{-1},$$  \hspace{1cm} (34)

which was associated with slightly (20%) higher rates than those fitted at the flume inlet:

$$\alpha_1 = 0.19, \lambda_1 = 5.8 \text{ s}^{-1}, \alpha_2 = 0.81, \text{ and } \lambda_2 = 15.2 \text{ s}^{-1}.$$  \hspace{1cm} (35)

To compute the sample mean and variance for the time series $(t_i, n_i)$, we used the bootstrap method and generated $M = 100$ samples from the experimental dataset (see §2.7). If the process was stationary and Poissonian with rate $\Lambda$, then we would expect that

$$(\bar{\Phi}_s) \rightarrow \Lambda \text{ and } \text{var } \bar{\Phi}_s(\Delta t) \rightarrow \frac{\Lambda}{\Delta t},$$  \hspace{1cm} (36)

as seen in §2.3. The parameter $\Lambda$ was estimated by fitting an exponential distribution to the waiting times between two positive jumps (that is, events for which $n_i > 0$) in the time series $(t_i, n_i)$. We found $\Lambda = 9.77$ s$^{-1}$. Note the slight difference (2%) in the mean transport rate calculated using the assumption of a Poisson process ($\bar{\Phi}_{ss} = \Lambda = 9.77$ grains/s) and the one obtained empirically by setting $\bar{\Phi}_{ss} = \bar{\Lambda} = N_{\text{tot}}/T_{\text{exp}} = 9.98$ grains/s. As shown in Fig. 4(b), the process was not a genuine Poisson process, and this led to small errors. This explains why the empirical means computed using the bootstrap method were close to the mean flux value $\bar{\Phi}_{ss} = \bar{\Lambda} = 9.98$ grains/s (see Fig. 5(a)), and 2% higher than the rate $\bar{\Lambda}$ deduced from the waiting-time distribution. For the variance $\text{var } \bar{\Phi}_s(\Delta t)$, Fig. 5(b) shows the excellent agreement between the variances computed using the bootstrap method and the theoretical prediction (36).

We also used renewal theory for computing the particle flux (see Appendix B). Here, we used the hyper-exponential distribution to estimate the waiting time between two events. The number of particles which could arrive at the same time was estimated using the binomial-like distribution (B1). From the experimental data, we deduced that there was a probability of $p = 11, 473/11, 989 = 0.979$ that a single particle crossed $S$ within $\delta t$, and of $1-p$ that two particles crossed it at the same time. This resulted in a flux average (B11) that closely matched the feed rate $\bar{\Lambda} = 9.98$ grains/s, as shown in Fig. 5(a). This confirmed that the slight discrepancy between theory and experiment was likely due to the existence of much longer waiting times than predicted by the exponential distribution. For the variance, our renewal model provided only the asymptotic scaling (B12):

$$\text{var } \bar{\Phi}_s \approx 15.2/\Delta t \text{ grains}^2/\text{s}^2,$$

which resulted in the right trend (var $\bar{\Phi}_s \propto (\Delta t)^{-1}$), but overpredicted variance by 50%. This may seem surprising—because the renewal model performed better than the Markovian model at predicting the sample mean in Fig. 5(a) — but it should be remembered that Eq. (B12) is an asymptotic expression that holds for sufficiently long times $\Delta t$. Further simulations (not shown here) of the renewal process, presented in Appendix B, confirmed the sample variance’s sensitivity to sample size.

### 4.3 Volume-Averaged Transport Rate

We recorded the number $N$ of moving particles in each frame. The time-averaged number of moving particles was $\bar{N} = 5.47$, whereas the variance was $\text{var } N = 11.5$. 

-17-
Figure 5. (a) Influence of sampling duration on the computation of the sample mean. The solid red line is the theoretical mean value given by Eq. (36), while the dashed red lines show the uncertainty domain $\langle \Phi_{ss} \rangle_{ss} \pm \text{var} \Phi_{ss}$. The dotted blue line is the empirical mean flux $\Phi_{ss} = \dot{\Lambda} = N_{tot}/T_{exp} = 11,974/1200 = 9.98 \text{ grains/s}$. (b) Influence of sampling duration on the sample variance. For both plots, the blue dots were obtained using the bootstrap method. The solid red line shows the theoretical variance (9) with $\Lambda = \hat{\Lambda} = 9.98 \text{ grains/s}$, whereas the dashed blue curve shows the variance (B12) derived from the renewal model.
Figure 6. (a) Comparison between the empirical (blue dots) and theoretical (red squares) negative binomial probability densities (11). (b) Autocorrelation function of $N(t)$: the black dots are the empirical function, and the solid red line shows the theoretical exponential function (13) with $t_c = 221$ ms. (c) Stationarity tests on the $(t_i, q_i)$ time series: the solid line shows $\sum_i q_i \delta t$, whereas the dashed line is the cumulative mass $\tilde{q}_{ss}$ with $\tilde{q}_{ss} = 10.27$ grains/s the bedload transport rate averaged over the run duration. (d) Particle velocity distribution: in addition to the histogram, we have plotted the Gauss–Laplace distribution (5) fitted to the data (solid blue line).

Figure 6(a) shows that the negative binomial model closely matched the statistical distribution of the number of particles moving in the window during time interval $\delta t$. The error was usually less than 6%, except at $n = 0$ where it reached 30%. The time series shows large fluctuations in $N$, with peaks as large as $5N$. Figure 6(b) shows that the exponential autocorrelation function (13) fitted the empirical autocorrelation function if we set $t_c = 221$ ms. The particles moved at a mean velocity $\bar{u}_p = 13.45$ cm/s (standard deviation $\sigma_u = 3.76$ cm/s). The Gauss–Laplace distribution offers a rough description of particle velocity fluctuations (see Fig. 6(d)). The stationarity test confirmed that the $(t_i, q_i)$ was a stationary process, with a mean rate $\tilde{q}_{ss} = 10.27$ grains/s.

We used the bootstrap method to evaluate how the sample mean $\langle \tilde{q}_s \rangle$ and variance $\text{var} \tilde{q}_s$ were dependent on sampling duration $\Delta t$. As the autocorrelation time $t_c = 221$ ms was fairly long compared to the acquisition time $\delta t = 4$ ms ($t_c/\delta t \sim 50$), we had to resample the raw data series $(t_i, N_i)$ at a frequency of $1/(50\delta t) = 5$ Hz to obtain a sample of independent and identically distributed data. Figure 7(a) shows that the mean computed using the bootstrap method was close to 10.25 grains/s, a slightly (2%) higher value than the time-averaged flux $\langle \Phi_s \rangle_{ss} = 9.98$ grains/s. Figure 7(b) shows the excellent agreement between the sample variances and their theoretical prediction (18). Because the velocity fluctuations here were small compared to their mean, taking velocity fluctuations into account did not lead to better results. This confirmed the observation, made by a number of authors (Cudden & Hoey, 2003; Ancy et al., 2008; Singh et al., 2009; Campagnol et al., 2012), that bedload transport fluctuations originate primarily from variations in the number of moving particles rather than from their velocities.
Figure 7. (a) Influence of the sampling duration $\Delta t$ on the computation of the sample mean: the black dots show the values generated using the bootstrap method. The solid red line shows the theoretical value (15). (b) Influence of the sampling duration on the computation of the sample variance. The solid red line shows the theoretical prediction (18) when assuming $\sigma_u = 0$ (i.e., velocity fluctuations are negligible), whereas the dashed red curve shows the theoretical prediction (25) when $\sigma_u > 0$. The latter curve is hardly discernable from the former as $\sigma_u \sim 0.07\bar{u}_p^2$. 
Figure 8. (a) Time variations in the time-averaged transport rate $\bar{q}_s$ (solid red line) and particle flux (dashed black line) $\bar{\Phi}_s$ for a sampling duration $\Delta t = 250 \delta t = 1$ s. (b) Relative difference between $\bar{q}_s$ and $\bar{\Phi}_s$ as a function of time $t$ for $\Delta t = 1$ s. (c) Time variations in the time-averaged transport rate $\bar{q}_s$ (solid red line) and particle flux (dashed black line) $\bar{\Phi}_s$ for a sampling duration $\Delta t = 2500 \delta t = 10$ s. Relative difference between $\bar{q}_s$ and $\bar{\Phi}_s$ as a function of time for $\Delta t = 10$ s.

4.4 Influence of the Sampling Duration on the Time Series

When comparing the means and variances of the particle flux (§ 4.2) and volume-averaged transport rate (§ 4.3), we found that the two definitions led to similar values (to within a few percent) and the same dependence on the sampling duration $\Delta t$. Although this finding made sense intuitively, it was not easy to anticipate it from the theoretical results in § 2.

This similarity holds only on average. As shown by Fig. 8, time series aspects depend a great deal on the definition of $q_s$ and the sampling duration. Using short sampling durations, the particle flux showed wide fluctuations as there was no time correlation between the two measurements. On the contrary, the bedload transport rates were correlated because the acquisition frequency was much higher than $1/t_c \sim 5$ Hz. Using longer sampling durations (typically for $\Delta t \geq 1$ s), the two time-averaged time series look generally similar. For $\Delta t = 1$ s, instantaneous differences $\epsilon = \bar{q}_s/\bar{\Phi}_s - 1$ exceeding 100% were observed (see Fig. 8(b)), and, on average, the mean difference $\bar{\epsilon}$ reached 7%. For $\Delta t = 10$ s, the relative differences were usually less than 20%, whereas the mean difference between the two time-series dropped below 3%.

4.5 The Influence of Bedforms

Bedforms developed along the bed downstream of the observation plate covering the free surface. Forms were likely exacerbated by the plate as we observed a clear difference in behavior upstream and downstream of it:
• Downstream of the plate, we observed upstream-migrating antidunes. Their wavelength ranged from approximately 8 cm to 15 cm, and their amplitude was close to 2 \(d_0\). Their celerity was in the 1–1.5-mm/s range, but they moved intermittently.

• Upstream of the plate, behavior was more complicated. Bed undulations were observed, but their origin and nature remained uncertain (perhaps they were sediment waves). Their wavelength fluctuated widely from 4 cm to 8 cm, and their amplitude was approximately one grain diameter. These forms experienced cycles of growth and decay over timescales of a few minutes, with no evidence of migration (see movie S2).

We also measured an 11% increase in the bedload transport rate: over 20 min, a total of 13,271 particles left the flume, whereas 11,974 crossed the control surface \(S\) located in the middle of the flume. The \(\Phi_s\) time series was more intermittent: pulses of intense activity were separated by periods of lower activity, which was also reflected in longer waiting times between particle arrivals (waiting times as long as 6 s were measured) as shown by Fig. 9(a). Examining time variations in the cumulative amount of sediment shows that during the first 6 min, the particle flux was much higher than the feed rate (16.3 grains/s versus 10.3 grains/s, on average, at the flume inlet) (see Fig. 9(b)). After a phase that lasted about 100 s (between \(t = 340\) s and 440 s) and during which the mean particle flux dropped to 2.7 grains/s, there was a period 440 \(\leq t \leq 1080\) s during which the particle flux remained almost constant (\(\Phi_s = 10.2\) grains/s) and close to the feed rate. We thus extracted a reduced sample between the timepoints 440 \(\leq t \leq 1080\) s.

Figure 9(c) shows that the double-averaged means (estimated using the bootstrap method) tended towards the mean particle flux \(\hat{\Lambda}_r = N_r/640 = 10.77\) grains/s obtained by dividing the number of particles \(N_r = 6896\) leaving the flume between timepoints \(t = 440\) s and \(t = 1080\) s, by the length of time 1080 – 440 = 640 s. As expected, the bootstrap method provided a correct estimate of the mean particle flux for this period. As the waiting-time distribution deviated from the exponential distribution, the particle rate deduced from the mean waiting time, \(\tilde{\Lambda}_r = 9.87\) grains/s, underestimated the actual transport rate by 8%. Applying the renewal model (B11) led to a mean transport rate \(\hat{\Phi}_s = 10.66\) grains/s, which was 1% below the actual rate. The main effect of bedforms was thus to alter the temporal distribution in the number of particles: the temporal distribution deviated gradually from the Poisson distribution as a result of increased intermittency, that is, alternating between periods during which no transport occurred and periods during which more intense sediment transport took place. Figure 9(d) shows that the double-averaged variance varied as \(\hat{\Lambda}_r/\Delta t\), as expected.

The forms observed upstream of the plate were likely driven by alternate phases of sediment storage (over periods spanning tens of seconds) and fast release of particle clusters. It is probable that this alternation changed the waiting-time distribution in the control window and created the hyper-exponential tail shown in Fig. 4(b). Downstream of the plate, the antidune migration period (in the 80–150-s range) was consistent with the time intervals between the bedload flux pulses recorded at the flume outlet (Fig. 1). We believed that the hyper-exponential waiting-time distribution at the flume outlet (Fig. 9) was due to antidune migration.

5 Applications

We finish the paper by describing two potential applications for the measurement protocol outlined in § 2.7:

• We ran long-duration experiments under steady-state conditions in a laboratory flume (see § 5.1). As gravel bars and pools developed and migrated along the flume bed, the bedload transport measured at the flume outlet exhibited wide fluctu-
Figure 9. (a) Waiting-time distribution at the flume outlet: dots show the empirical probabilities. The solid red line is the exponential distribution (6) with rate $\lambda = 10.0$ grains/s. The dashed black line shows the hyper-exponential distribution (33) fitted to the data. The dotted blue line shows the hyper-exponential distribution (35) adjusted to the flume inlet data. (b) Stationarity test: time variation in the cumulative number of particles crossing the control surface $\sum_0^t \phi(x(\tau))\Delta t$. The red line is the mean behavior $\bar{\Lambda}$ with $\bar{\Lambda} = 13,271/1200 = 11.06$ grains/s. The dashed vertical lines show the period (from 440 s to 1080 s) over which the particle flux could be considered stationary. (c) Variations in the double-averaged particle flux with the sampling duration $\Delta t$. The solid red line shows the mean particle flux $\bar{\Lambda}_r = N_r/640 = 10.77$ grains/s obtained by dividing the number of particles $N_r = 6896$ leaving the flume between times $t = 440$ s and $t = 1080$ s. The dashed red line shows the mean particle flux defined from the waiting-time distribution by adjusting the exponential distribution (6) using the reduced sample, with $\bar{\Lambda}_r = 9.87$ grains/s. The dashed blue line shows the mean $\bar{\Phi}_r = 10.66$ grains/s, computed using the renewal model (B11), with $p = 0.92$, $\lambda_1 = 3.59$ 1/s, $\lambda_2 = 14.69$ 1/s, $\alpha_1 = 0.16$, and $\alpha_2 = 0.84$. The blue points show the sample averages computed using the bootstrap method and the reduced sample as the training sample. The grey points show the sample averages when the entire time series is used as the bootstrap method’s training sample. (d) Variation in the double-averaged variance $\text{var} \bar{\Phi}_r$ with the sampling interval $\Delta t$. The solid red line shows the theoretical variance (9) with $\Lambda = \bar{\Lambda} = 10.0$ grains/s.
ations resulting from alternating phases of low and intense transport. Bedload transport pulses were often associated with the destruction of bars, which released large amounts of gravel (Dhont & Ancey, 2018).

• We have been monitoring a gravel-bed river in the Swiss Alps since 2011 (see § 5.2). Contrary to other applications in this paper, this was not a steady-state system, but there were periods during which it approached a steady state, which made it possible to apply our measurement protocol.

These two applications illustrate the sampling duration’s significance to the estimation of bedload transport rates. To obtain fairly high precision (10% variance or lower), one has to carefully study how the $Q_s$ variance changes with the sampling duration $\Delta t$.

5.1 Laboratory Flume

Here, we show how the measurement protocol performed with a time series of bedload transport rates measured at the outlet of a flume 19 m long, 60 cm wide, and inclined at 1.6% to the horizontal. We used gravel whose median diameter was $d_{50} = 5.5$ mm. The water discharge was constant $Q_w = 15$ L/s. Transport rates were measured using impact plates and accelerometers operated at 100 Hz for a long period ($T_{exp} = 155$ h). Raw data were aggregated by averaging them over time steps of $\delta t = 1$ min. The reader is referred to Dhont (2017) and Dhont and Ancey (2018) for details of this experiment.

Figure 10(a) shows the bedload transport rate recorded at the flume outlet: periods of intense bedload transport were usually associated with the destruction of gravel bars or the scouring of pools. Despite these pulses, the overall bedload transport rate behaved like a quasi-stationary process, as shown by Fig. 10(b). Applying the central limit theorem enabled us to estimate how the time-averaged mean and variance varied with sampling duration $\Delta t$, whereas the bootstrap method enabled us to generate double-averaged means and variances for different $\Delta t$ values (see Figs. 10(c) and (d)). Although the central limit theorem provides only an asymptotic expression for var $\bar{Q}_s$ ($\text{var } \bar{Q}_s = \sigma_q^2 \delta t / \Delta t$), we found that for all $\Delta t$ values, this asymptotic relation closely matched the sample generated using the bootstrap method. Figure 10(d) shows that for a sampling duration $\Delta t = 1$ min, the variance was $4.3 \text{g}^2/\text{s}^2$, and thus we could only determine the mean bedload transport rate to within $\sqrt{4.3/4.07} \sim 50\%$. If we wanted greater precision in the determination of $Q_s$—say 10% greater precision—we had to increase the sampling duration to 30 min, as per Fig. 10(d).

5.2 Gravel-Bed River

Here, we present an application to the River Navisence (canton Valais, Switzerland), a gravel-bed river near Zinal monitored since 2011. Bedload transport rates are measured using geophones placed across a concrete sill of width $W = 9$ m (Ancey et al., 2014; Wyss et al., 2016). The mean bed slope upstream of the sill is $i = 3.2\%$. The median particle diameter of transported bedload was $d_{50} = 8$ cm.

Figure 11(a) shows the time series of bedload transport rates $Q_s$ and water discharge $Q_w$ for 8 July 2012 (a day picked randomly). Water discharge varied throughout the day under the effect of sunshine. Overnight and in the morning, bedload transport rates were negligibly low. In the afternoon, ice- and snow-melt increased water discharge and thus the transport rate went up. We isolated a sequence of transport rates from 17:00 to 18:00, for which bedload transport could be considered stationary, as shown by Fig. 11(b).

Figures 11(c) and (d) show the double-averaged means and variances computed using the bootstrap method. As the bedload transport was stationary during the period considered, the double-averaged means were close to the mean rate $Q_{ss} = \bar{\Lambda} = 236$ g/s estimated using the stationarity test (see Fig. 11(b)). The variance curve in Fig. 11(d)
Figure 10. Application to a 19–m-long flume. (a) Time series of $\tilde{\Phi}_s$. (b) Stationarity test. The dashed red line is the cumulative sediment mass $\int Q_s \, dt = \hat{\Lambda} t$ with $\hat{\Lambda} = 4.07$ g/s. (c) Variation in the double-averaged mean with the sampling duration $\Delta t$. The solid red line shows the mean flux $\bar{Q}_{ss} = \hat{\Lambda} = 4.07$ g/s, whereas the black dots show the means generated using the bootstrap method. (d) Variation in the double-averaged variance with sampling duration $\Delta t$. The black dots show the variances generated using the bootstrap method. The solid red line is the theoretical variance $\text{var} \bar{Q}_s = \sigma_q^2 \delta t / \Delta t$ with $\sigma_q^2 = 4.8 \, \text{g}^2/\text{s}^2$. 

\begin{align*}
\text{var} \bar{Q}_s & = \sigma_q^2 \delta t / \Delta t \\
\sigma_q^2 & = 4.8 \, \text{g}^2/\text{s}^2
\end{align*}
Figure 11. Application to the River Navisence. (a) Time series for 8 July 2012. The inset shows the time variations in the water discharge $Q_w$, while in the main graph, we have plotted the $Q_s$ time series for 8 July 2012 ($Q_s$ has been averaged over time steps of $\delta t = 1$ min (Ancey et al., 2014; Wyss et al., 2016). From this time series, we extracted a sample from from 17:00 to 18:00 (represented by the vertical dashed lines). (b) Stationarity test. The dashed red line is the cumulative mass $\int Q_s \, dt = \hat{\Lambda} t$ with $\hat{\Lambda} = 236$ g/s. (c) Variation in the double-averaged mean with the sampling duration $\Delta t$. The solid red line shows the mean flux $\bar{Q}_s = \bar{\Lambda} = 236$ g/s, whereas the black dots show the means generated using the bootstrap method. (d) Variation in the double-averaged variance with sampling duration $\Delta t$. The black dots show the variances generated using the bootstrap method. The solid red line is the theoretical variance $\text{var} \bar{Q}_s = \sigma_q^2 \delta t / \Delta t$ with $\sigma_q^2 = 7536$ g$^2$/s$^2$. 
enabled us to estimate that for $\Delta t = \delta t = 60$ s, the mean transport rate was accurate to within $\sigma_q/\bar{Q}_s = 36\%$. Increasing $\Delta t$ by a factor of 10 ($\Delta t = 10 \text{ min}$) decreased the uncertainty to 3.6%. As the 17:00 to 18:00 time slot corresponded to the day’s peak bedload transport activity, it is tempting to consider that a convenient sampling duration for 8 July 2012 was $\Delta t = 10 \text{ min}$—sufficiently long to obtain low var $\bar{Q}_s$ values and sufficiently short to capture the slow variations in the bedload transport rate with water discharge.

6 Conclusion

Bedload transport rates usually exhibit wide fluctuations, even under steady flow conditions. Measurements of time-averaged transport rates $\bar{Q}_s$ representative of bedload transport at given times can thus be biased to varying degrees, as illustrated by Fig. 1, where errors exceeding 100% can be observed at certain sampling durations.

The present paper examines how we can assess the uncertainties associated with estimating a time-averaged transport rate $\bar{Q}_s$. We used the birth–death immigration–emigration model developed by Ancey et al. (2008). We arrive at an experimental protocol for measuring the mean particle flux $\bar{q}_s = \Phi_s$ or bedload transport rate $\bar{Q}_s = \bar{q}_s$ (see §2.7) and estimating the uncertainties associated with that measurement. The first step is to define a time interval over which $\bar{Q}_s(t)$ behaves like a stationary process. Depending on the data acquisition frequency and the relevance of the Markovian assumption (waiting times distributed exponentially or exhibiting a thicker tail), different models can be used to define the double-averaged mean and variance. When data-acquisition frequencies are sufficiently high (typically, higher than 1 Hz) and the Markovian assumption is realistic, then the Markovian model developed by Ancey et al. (2008) can be applied. When the Markovian assumption fails, a renewal model can be used. At low data acquisition frequencies, the central limit theorem can be employed to find the double-averaged variance’s dependence on the sampling duration $\Delta t$.

Markov process theory provides valuable insights into the behavior of $\bar{Q}_s$ fluctuations. One remarkable result is that the ensemble variance of $\bar{Q}_s$ is controlled solely by the sampling duration $\Delta t$ and mean rate $\bar{Q}_s$. As exemplified by the toy model in Section 1.3, this ensemble variance offers a better estimate of the uncertainties associated with the measurement of $\bar{Q}_s$ than does sample variance.

Acknowledgments

**Appendix A Integral of a Markov Process**

**A1 Theoretical Reminder: Master Equations and Other Definitions**

We assume that the time variations in \( N \) can be described using Markov process theory (Gillespie, 1992). Between times \( t \) and \( t + dt \), the \( N \) variation (called the propagator)

\[
\Theta(dt; n, t) = N(t + dt) - N(t) \text{ given that } N(t) = n, \quad (A1)
\]

has the following probability density function (strictly speaking, the probability mass function as \( N \) is a discrete random variable):

\[
\Pi(m|t; n, t) = \text{prob} (\Theta(dt; n, t) = m), \quad (A2)
\]

with \( m = 0, 1, \) or \(-1\) for a birth–death Markov process. The process can be also described by introducing the jump probability \( q(n, t; \tau) \), which is the probability that \( N \) varies by \( \pm 1 \) at some instant between \( t \) and \( t + \tau \). The Markovian assumption imposes that for infinitesimal time intervals, \( q(n, t; dt) = a(n, t)dt \), where \( a \) is a positive function of \( n \) and \( t \). The state probability \( w(m|n, t) \) is the probability that upon jumping at time \( t \), \( N \) takes the new value \( n + m \). The propagator density \( \Pi \) and the functions \( a \) and \( w \) are related:

\[
\Pi(m|t; n, t) = a(n, t)dtw(m|n, t) + (1 - a(n, t)dt)\delta_k(m, 0), \quad (A3)
\]

where \( \delta_k \) is the Kronecker delta function.

We also define the consolidated characterizing function:

\[
W(m|n, t) = a(n, t)tw(m|n, t), \quad (A4)
\]

which can be interpreted as follows: \( Wdt \) is the probability that the number of particles \( N(t) = n \) jumps from \( n \) to \( n + m \) in the time interval \( dt \). This function can be used in the master equation, that is, the governing equation for the probability of observing \( N(t) \):

\[
\frac{\partial}{\partial t} P(n, t|n_0, t_0) = \sum_{m=-1}^{m=+1} W(m|n-m, t)P(n-m, t|n_0, t_0) - W(-m|n, t)P(n, t|n_0, t_0), \quad (A5)
\]
and if we define

\[ W_+(n) = W(1|n, t) \text{ and } W_-(n) = W(-1|n, t), \]  
(A6)

which are the probabilities of gain or loss, respectively, then the master equation (A5) can also be written

\[ \frac{\partial}{\partial t} P(n, t|n_0, t_0) = W_-(n + 1)P(n + 1, t|n_0, t_0) - W_+(n)P(n, t|n_0, t_0) + W_+(n - 1)P(n - 1, t|n_0, t_0) - W_-(n)P(n, t|n_0, t_0). \]  
(A7)

It can be shown that the process is entirely determined by the functions (Gillespie, 1992):

\[ a(n) = W_+ + W_- = v_{in} + \lambda + (v_{out} + \mu + \sigma)n, \]  
(A8)

where \( a(n)dt \) represents the probability that \( N \) varies within the time period \( dt \), and

\[ v(n) = W_+ - W_- = v_{in} + \lambda + (\mu - \sigma - v_{out})n. \]  
(A9)

Equivalently, we can work with the pairs of functions \((W_+, W_-)\) or \((a, v)\).

### A2 Mean, variance and covariance of \( N(t) \)

It can be shown that the mean number of moving particles \( \langle N \rangle \) satisfies the differential equation (see Chap. 6 in Gillespie (1992)):

\[ \frac{d}{dt} \langle N \rangle = v\langle N \rangle = W_+\langle N \rangle - W_-\langle N \rangle, \]  
(A10)

subject to the initial condition \( \langle N \rangle(t_0) = N_0 \). The variance of \( N \) is governed by

\[ \frac{d}{dt} \text{var} N = 2\langle Nv(N) \rangle - \langle N \rangle \langle v(N) \rangle + \langle (a(n)) \rangle, \]  
(A11)

subject to \( \text{var} N(t_0) = 0 \). The time covariance is

\[ \frac{d}{dt_2} \text{cov} (N(t_1), N(t_2)) = \langle N(t_1)v(N(t_2)) \rangle - \langle N(t_1) \rangle \langle v(N(t_2)) \rangle, \]  
(A12)

for \( t_0 \leq t_1 \leq t_2 \) and subject to the initial condition \( \text{cov} (N(t_1), N(t_1)) = \text{var} N(t_1) \).

### A3 Integral \( S \) of \( N(t) \)

The time integral \( S \) of \( N \) is defined as

\[ S(t) = \int_{t_0}^{t} N(t)dt. \]  
(A13)

Its mean value is given by

\[ \frac{d}{dt} \langle S \rangle = \langle N \rangle, \]  
(A14)

whereas the time variations in the covariance \( \text{cov} (S, N) = \langle SN \rangle - \langle S \rangle \langle N \rangle \) obey the equation

\[ \frac{d}{dt} \text{cov} (S, N) = \text{var} N + \langle Sv(N) \rangle - \langle S \rangle \langle v(N) \rangle, \]  
(A15)

subject to \( \text{cov} (S, N) = 0 \) at time \( t = t_0 \). The \( S \) variance is

\[ \frac{d}{dt} \text{var} S = 2\text{cov} (S, N), \]  
(A16)

subject to \( \text{var} S(t_0) = 0 \). The covariance of \( S \) is the solution to

\[ \text{cov} (S(t_1), S(t_2)) = \text{var} S(t_1) + 2\int_{t_1}^{t_2} \text{cov} (S(t_1), N(\tau))d\tau \]  
(A17)

for \( t_0 \leq t_1 \leq t_2 \) and where the integrand is the solution to the differential equation

\[ \frac{d}{dt_2} \text{cov} (S(t_1), N(t_2)) = \langle S(t_1)v(N(t_2)) \rangle - \langle S(t_1) \rangle \langle v(N(t_2)) \rangle, \]  
(A18)

for \( t_0 \leq t_1 \leq t_2 \). We refer the reader to Chapter 6 in Gillespie (1992) for the proofs.
A4 Moments of $S$

The mean time integral $S$ is the solution to Eq. (A14)

$$
\langle S(t) \rangle = N_0 t_c (1 - e^{-t/t_c}) + \langle N \rangle_{ss} \left( t - t_c (1 - e^{-t/t_c}) \right).
$$

(A19)

The solution to the covariance equation (A15)

$$
\frac{d}{dt} \text{cov} (S, N) = \text{var} N - \alpha \text{cov} (S, N),
$$

takes the form

$$
\text{cov} (S, N) = \frac{N_0 \gamma}{\alpha^2} \left( e^{-2t/t_c} + e^{-t/t_c} (at - 1) \right) + \frac{\beta (1 - e^{-t/t_c})^2 + \gamma \langle N \rangle_{ss} (1 - 2at e^{-t/t_c} - e^{-2t/t_c})}{2\alpha^2},
$$

(A20)

where $\gamma = \nu_{\text{out}} + \sigma + \mu$ and $\alpha = \nu_{\text{out}} + \sigma - \mu$. We find that the covariance tends to the limit

$$
\text{cov}_{ss} (S, N) = \frac{\beta + \gamma \langle N \rangle_{ss}}{2\alpha^2} = \frac{(\lambda + \nu_{\text{in}})(\nu_{\text{out}} + \sigma)}{(\nu_{\text{out}} + \sigma - \mu)^3}.
$$

(A21)

Using Eq. (A16), we deduce the variance of $S$ by integrating the covariance $\text{cov} (S, N)$.

Asymptotically, this scales as

$$
\text{var} S \propto \frac{\beta + \gamma \langle N \rangle_{ss}}{\alpha^2} t = \frac{(\lambda + \nu_{\text{in}})(\nu_{\text{out}} + \sigma)t}{(\nu_{\text{out}} + \sigma - \mu)^3}.
$$

(A22)

By solving Eq. (A17), we find that the autocorrelation function of $S$ is

$$
\rho_s (\tau) = 1 + \frac{t_c}{\tau} \frac{(\nu_{\text{out}} + \sigma - \mu)^3}{(\lambda + \nu_{\text{in}})(\nu_{\text{out}} + \sigma)} (1 - e^{-\tau/t_c}).
$$

(A23)

Appendix B Time-Averaged Particle Flux: Renewal Theory

The Markovian assumption imposes strict conditions on the applicability of Eq. (8). These are either an exponential distribution for the waiting times or, equivalently, a Poisson process for the number of particles crossing the control surface. We can relax these assumptions by considering other probability distributions and using renewal theory to compute the number of particles crossing the control surface $S$. Let us consider that one or two particles can arrive at the same time:

$$
\begin{align*}
\text{prob} (N = 1) &= p, \\
\text{prob} (N = 2) &= 1 - p, \\
\text{prob} (N > 2) &= 0,
\end{align*}
$$

(B1, B2, B3)

and that the waiting-time distribution is the two-parameter hyper-exponential distribution, whose density function is

$$
P_t (\tau) = \alpha_1 \lambda_1 \exp(-\lambda_1 \tau) + \alpha_2 \lambda_2 \exp(-\lambda_2 \tau),
$$

(B4)

where $\alpha_1$ and $\alpha_2$ are mixture parameters satisfying $\alpha_1 + \alpha_2 = 1$, whereas $\lambda_1$ and $\lambda_2$ are two rates. At time $t$, $M$ jumps have occurred (with one or two arrivals). Let us call $S$ the sum of particles that have crossed the control surface up to time $t$

$$
S(t) = \sum_{i=1}^{M(t)} N_i
$$

(B5)

where $M(t) = \max \{ n : T_n \leq t \}$, and $T_n = \tau_1 + \tau_2 + \cdots + \tau_n$ for $n \geq 1$ ($T_0 = 0$), and $\tau_i$ is a sequence of waiting times distributed from (B4). There is no analytical expression
of $S$ in (B5), but we can derive approximations in the limit of $t \to \infty$. Using Wald’s equation (Grimmett & Stirzaker, 2008), we can deduce the expectation of the sum $S$:

$$E(S) = E(N)E(M),$$

and using the law of total variance, we get its variance:

$$\text{var } S = \text{var } NE(M) + E(N)^2 \text{var } M.$$  

Here we have: $\text{var } N = p(1 - p)$ and $E(N) = 2 - p$. The number of jumps can be approximated as follows:

$$E(M) = \frac{t}{\bar{r}} + o(t),$$

$$\text{var } M = \frac{t\sigma^2}{\bar{r}^2} + o(t),$$

with

$$\bar{r} = \frac{\alpha_1}{\lambda_1} + \frac{\alpha_2}{\lambda_2}$$

and

$$\sigma^2 = 2\left(\frac{\alpha_1}{\lambda_1^2} + \frac{\alpha_2}{\lambda_2^2}\right) - \left(\frac{\alpha_1}{\lambda_1} + \frac{\alpha_2}{\lambda_2}\right)^2.$$ 

We then deduce:

$$\Phi_s(t) = E\left(\frac{S}{t}\right) = (2 - p)\frac{\lambda_1 \lambda_2}{\lambda_2 \alpha_1 + \lambda_1 \alpha_2},$$

and

$$\text{var } \Phi_s(t) = \text{var } \left(\frac{S}{t}\right) = \left(\frac{p(1 - p)}{\bar{r}} + \frac{(2 - p)^2 \text{var } \tau}{\bar{r}^3}\right) \frac{1}{t}.$$ 

**Appendix C  Exponential Velocity Distribution**

Let us consider that the particle velocity is distributed exponentially. We then replace the Gaussian distribution (5) with the exponential law with mean $\bar{u}_p$.

$$P_u(w) = \text{prob}(u = w) = \frac{1}{\bar{u}_p} \exp(-w/\bar{u}_p).$$

Like in § 2.5, we introduce the sum of $k$ particle velocities

$$U = \sum_{i=1}^{k} u_{p,i}.$$ 

If $k$ is fixed, then the probability $P_k$ of observing $U$ is the Erlang distribution with shape $k$ and rate $1/\bar{u}_p$. If $k$ varies randomly, then the probability of observing $U$ is

$$P_U = \sum_{k=1}^{\infty} P_n(k)P_k(U).$$

The volume-averaged transport rate is $q_s = U/L$. If we still assume that the probability of observing $k$ particles is given by the negative binomial distribution with parameters $p$ and $q$, the probability distribution of $U$ becomes

$$P_{qs} = LP_U(Lqs) = L \sum_{k=1}^{\infty} \left(\frac{q + n - 1}{q - 1}\right) p^q(1 - p)^n \frac{(Lqs)^{k-1}e^{-Lqs/\bar{u}_p}}{\bar{u}_p^k(k-1)!}.$$ 

There exists a closed-form expression for $P_{qs}$, but we just need the first two moments:

$$\langle q_s \rangle = \int_{R^+} q_s P_{qs} dq_s = \frac{N_{ss}}{L} \bar{u}_p,$$

$$\text{var } q_s = \int_{R^+} (q_s - \langle q_s \rangle)^2 P_{qs} dq_s = \frac{\text{var } s_{ss} N}{L^2}(1 + p)\bar{u}_p^2.$$
Assuming that particle velocity and particle number are independent variables, we can generalize the variance equation (18) to take velocity fluctuations into account in the double-averaged variance by following the same reasoning as that used for deriving Eq. (18):

$$\text{var} \bar{q}_s(\Delta t|t) = \text{var}_sN \bar{u}_p^2 (1 + p) \frac{t_c}{\Delta t},$$  \hspace{1cm} (C7)

an expression that is close to Eq. (25) obtained for Gaussian velocity distributions.
